ABSTRACT: This article presents a new method for fitting a digital line or plane to a given set of points in a 2D or 3D image in the presence of noise by maximizing the number of inliers, namely the consensus set. By using a digital model instead of a continuous one, we show that we can generate all possible consensus sets for model fitting. We present a deterministic algorithm that efficiently searches the optimal solution with time complexity O(N^2 log N) for dimension d, where d = 2, 3, together with space complexity O(N^2). The fitting is carried out through optimizing different cost functions. For instance, least-squares minimizes the geometric distances from all given points to the model. The solution can be obtained analytically, however it is not robust to the presence of outliers, namely points which do not fit the model. Least-absolute values uses the vertical distances, instead of the geometric distances, for its minimization. Some efficient iterative algorithms have been proposed in the literature. However, if there are outliers, the solution is known to be unstable. In contrast, LMS minimizes the median of the vertical/geometric distances of all given points to the model. Thus, the fitting is robust as long as fewer than half of the given points are outliers (Rousseeuw, 1984).

In this article, we present a novel globally optimal method that, given an arbitrary cloud of 2D or 3D points, finds the line or plane that minimizes the number of outliers, or alternatively maximizing the number of inliers, namely points which do fit the model, also called the consensus set. The idea of using such consensus sets was proposed for the RANdom SAMple Consensus (RANSAC) method (Fischler and Bolles, 1981), which is one of the most widely used in the field of computer vision. However RANSAC (and its variations) is inherently probabilistic in its approach, and do not guarantee any optimality while our method is both deterministic and optimal in the size of the consensus set. To guarantee the optimality of consensus sets, we follow a digital geometry (DG) methodology (Klette and Rosenfeld, 2004) by using a digital line and plane models (Reveille`s, 1991; Klette and Rosenfeld, 2004) instead of (1) and (2). This methodology is in fact natural given the assumption that our inputs are digital images. Besides, such a digital model allows us to distinguish between digitization-induced noise and actual noise. Related work using digital line or plane models can be found in works such as digital line or plane recognition (Buzer, 2003; Gerard et al., 2005; Buzer, 2006), digital curve polygonalization (Debled-Rennesson et al., 2006; Bhowmick and Bhattacharyya, 2007), and digital surface polyhedrization (Sivignon et al., 2004; Provot et al., 2006) with and without the presence of noise.
II. THE PROBLEM OF DIGITAL LINE AND PLANE FITTING

A line $L$ and a plane $P$ in the Euclidean space $\mathbb{R}^n$, $n = 2, 3$, are defined by (1) and (2). In this article, we use digital models, instead of continuous ones, for lines and planes in a discrete space $\mathbb{Z}^d$ for $d = 2, 3$, where $\mathbb{Z}$ is the set of all integers. We contend that using digital models is natural when our input data is a set of points in a digital space.

Figure 1. A digital line that has one critical point $p_1$ and its rotated digital line with a second critical point $p_2$. [Color figure can be viewed in the online issue, which is available at wileyonlinelibrary.com.]

However, to the best of our knowledge, outliers, namely points which do not fit the model, have never been studied in the field of DG.

This work is an extension of our previous papers on digital line fitting (Zrour et al., 2009a) and digital plane fitting (Zrour et al., 2009b). We can treat both the 2D and 3D problems by considering them in the dual space of the dual transform (De Berg et al., 2008). Indeed, we show that digital plane fitting in 3D can be treated with a similar methodology to the one for digital line fitting in 2D because it can be viewed as a 2D problem. We present an algorithm that has a time complexity of $O(N^d \log N)$ for the dimension $d = 2, 3$, with $N$ the number of points, and a space complexity $O(N)$. Note that the space complexity is not affected by the dimension. We also point out that there are degenerate cases since our inputs are only integers and all computations can be executed by using rational numbers alone, and present how we can deal with them.

The rest of the article is as follows: in Section II, we expose the framework of our digital model. In Section III, we prove the optimality of our result. In Sections IV and V, we provide an algorithm for the computation of the line fit in 2D and an extended algorithm for the plane fit in 3D, respectively. Section VI provides a method for extracting the parameters from the fit. Sections VII is devoted to 2D and 3D results and applications, respectively. Finally Section VIII states some conclusions and perspectives.

Figure 2. A digital line that has no critical point and its translated digital line with one critical point $p_1$. [Color figure can be viewed in the online issue, which is available at wileyonlinelibrary.com.]
coordinates, we easily notice that the number of different consensus sets for the digital line or plane fitting of $S$ is finite as well. Thus, if we can find all different consensus sets $C$ from a given $S$, we just need to verify the size of each $C$ and find the maximum one (ones if there are several) as the optimal solution.

Then the following question comes up naturally: is it possible to find all the consensus sets of $S$? If the answer is positive, how can we do it? In this section, we will answer these questions. For the followings, we give some notions related to digital lines and planes.

Two parallel lines (resp. planes) that are given by the equations in (3) (resp. (4)) are called the support lines (resp. planes) of a digital line (resp. plane). Discrete points that are on support lines (resp. planes) are called critical points of a digital line (resp. plane).

A. Digital Lines and Their Consensus Sets. We first attack the 2D case of digital line fitting.

**Proposition 1** Let $C$ be a consensus set of $S$ for a digital line. It is possible to find a new digital line whose consensus set is the same as $C$ such that it has at least two critical points.

**Proof** Let $D$ be an initial digital line that contains all points of $C$ as its inliers. Then, the following three cases can be considered when studying the critical points of $D$.

1. Suppose that $D$ has more than one critical points, then the proposition is already established in this case.
2. Suppose that $D$ has one critical point $P_1$. In this case, we apply a rotation to $D$ around $P_1$ until finding another point $P_2$ in $C$ so that $P_2$ becomes a critical point. The rotation is accomplished in such a way as to maintain the distance $w$ between the support lines, and so that the support line on which there is not $P_1$ is rotated around the point $P_2^*$ that is the projection of $P_2$ on the line. Figure 1 shows an example of a rotated digital line. Note that we can rotate $D$ either clockwise or counterclockwise.
3. Suppose that $D$ has no critical point. In this case, we first apply a translation to $D$ to find a first critical point $P_1$. Note that a translation can be made to any direction and the two support lines shall maintain the distance $w$ between them. During such a translation, if more than one points are detected as critical points, then the proof is complete. If just one point $P_1$ is detected, as illustrated in Figure 2, then a rotation is made around $P_1$ as mentioned in the previous case, in order to obtain a second critical point $P_2$.

From this proposition, we see that we can find a digital line $D(L)$ for any consensus set $C$ of $S$ such that it has at least two critical points. This is intuitively understandable, because when we move a digital line $D(L)$ in the image plane, its consensus set $C$ will change when a critical point goes out from $D(L)$, namely, becomes an outlier, due to the motion of the line. Indeed, such a digital line $D(L)$ can be constructed from a pair of points chosen from $S$ such that they become critical points of $D(L)$. Consequently, we can find all $C$ from those $D(L)$ constructed from pairs of points in $S$.

B. Digital Planes and Their Consensus Sets. Similarly to digital lines, we have the following proposition for digital planes.

**Proposition 2** Let $C$ be a consensus set of $S$ for a digital plane. It is possible to find a new digital plane whose consensus set is the same as $C$ such that it has at least three critical points.

**Proof** Let $D$ be an initial digital plane that contains all points in $C$ as its inliers. Then, the following four cases can be considered when observing the critical points of $D$.

1. Suppose that $D$ has more than two critical points, then the proposition is correct in this case.
2. Suppose that $D$ has two critical points $P_1$ and $P_2$, which may be located on one side or either side of the two parallel support planes of $D$. First, we take the projections $P_1^*$ (resp. $P_2^*$) of $P_1$ (resp. $P_2$) on the support plane where $P_1$ (resp. $P_2$) does not exist in the $z$-axis direction. We then apply a rotation to $D$ in such a way as to maintain the distance $w$ between the support planes until finding another point $P_3$ in $C$ so that $P_3$ becomes a critical point. To achieve this to the support plane where $P_1$ and $P_2$ exist, we apply a rotation around the line going through $P_1$ and $P_2$, as illustrated in Figure 3. To the other support plane, we apply a rotation around the line going through $P_1^*$ and $P_2^*$, as illustrated in Figure 3. In the case of Figure 4, similarly, to the support plane where $P_1$ (resp. $P_2$) exists, we apply a rotation around the line going through $P_1$ and $P_2$ (resp. $P_1^*$ and $P_2^*$). Note that we can rotate $D$ either clockwise or counterclockwise.
3. Suppose that $D$ has one critical point $P_1$. In this case, we also consider the projection of $P_1$, $P_1^*$. We then apply a rotation to each support plane until finding another point $P_2$ in $C$ so that $P_2$ becomes a critical point, as illustrated in Figure 5. The support plane where $P_1$ (resp. $P_1^*$) exists is rotated around any line going through $P_1$ (resp. $P_1^*$) on the support plane. If just one point $P_2$ is found as a second critical point after the rotation, then another rotation is made, as mentioned in the previous case, in order to obtain a third critical point $P_3$.
4. Suppose that $D$ has no critical point. In this case, we first apply a translation to $D$ to find a first critical point $P_1$. Note that a translation can be made in any direction while the two support planes maintain a constant distance $w$ between them. During such a translation, if more than two points are found as critical points, then the proof is complete. If just one point $P_1$ is found, as illustrated in Figure 6, then we follow the previous case.
From this proposition, similarly to the 2D case, we see that we can find a digital plane $D(P)$ for any consensus set $C$ of $S$ such that it has at least three critical points. Consequently, we can find all $C$ from $D(P)$ constructed from all possible triplets of points in $S$.

IV. DIGITAL LINE FITTING ALGORITHM

We first describe the digital line fitting problem in the dual space of the duality transform (De Berg et al., 2008), because our algorithm works in the dual space. We then present an algorithm to exhibit the optimal consensus set (or sets if the solution is not unique) that maximizes the number of inliers of a fitted digital line from a given set $S$ of 2D discrete points, step by step. We also describe special treatments for degenerate cases; it should be noted that digital images likely present many degenerate cases that must be processed separately.

A. Digital Line Fitting in the Dual Space. Our algorithm is inspired by the algorithm of LMS (Souvaine and Steele, 1987) working in the dual space of the following duality transform (De Berg et al., 2008): let $p = (x_p, y_p)$ be a 2D point in the primal space $(x, y)$ then the dual of $p$ is the line:

$$L^0_p = \{(a, b) : x_p a + b + y_p = 0\}$$

in the dual space $(a, b)$. Likewise, the dual of a nonvertical line $ax + y + b = 0$ in the primal space is the point $(a, b)$ in the dual space.

Now, let us consider the dual-space interpretation of a digital line in the primal space, defined by (3). A digital line is regarded as a set of parallel lines whose slopes are $-a$, and whose $y$-intercepts are between $-b$ and $w-b$. It corresponds, in the dual space, to a vertical line segment of length $w$ which is the distance between two parallel lines of the digital line, as illustrated in Figure 7. Because points in $S$ in the primal space are represented by lines in the dual space, the problem of finding the optimal consensus set in the primal space is equivalent to searching the best position of the vertical line in the dual space. This line forms an edge in the dual space.

Figure 7. A digital line of width $w$ in the primal space (left) corresponds to a vertical line segment of length $w$ in the dual space (right). [Color figure can be viewed in the online issue, which is available at wileyonlinelibrary.com.]

Figure 8. Digital lines on which a point $p$ is a critical point in the primal space (left), and those corresponding vertical line segments of length $w$ in the dual space (right). In the dual space, a set of all such digital lines forms two strips, each of which is bounded by two lines $L^0_p$ and $L^i_p$ for $i = 1, 2$. [Color figure can be viewed in the online issue, which is available at wileyonlinelibrary.com.]
B. Strips Made from a Critical Point. Obviously, we cannot search everywhere in the dual space to find the best line segment. From Proposition 1, we know that, for any consensus set, there exists a digital line that features at least two critical points. Therefore, we first take one point \( p \in S \), and consider it to be the first critical point of such a fitted digital line. Because \( p \) corresponds to a line \( L_p^0 \) in the dual space, all digital lines for which \( p \) is a critical point correspond to the set of all the vertical line segments of length \( w \) having one of its endpoints on \( L_p^0 \) in the dual space, as shown in Figure 8. The set of such digital lines, therefore, forms two strips in the dual space; one of them is bounded by \( L_p^0 \) and \( L_p^1 \), and another is bounded by \( L_p^0 \) and \( L_p^2 \), as illustrated in Figure 8. For simplification, we focus on the strip bounded by \( L_p^0 \) and \( L_p^1 \), because the following discussion is also valid for another strip bounded by \( L_p^0 \) and \( L_p^2 \).

C. Digital Lines with Critical Point Pairs. According to Proposition 1, we choose a point \( q \in S \setminus \{p\} \) to be the second critical point of a fitted digital line such that \( x_q \neq x_p \); the case of \( x_q = x_p \) will be discussed later. Any point \( q \) in the primal space is represented by the line \( L_q^0 \) in the dual space, as shown in Figure 9. We see in this figure that \( L_q^0 \) intersects each of the strip boundaries, \( L_p^0 \) and \( L_p^1 \), if it is not parallel to \( L_p^0 \). The parallel case occurs when \( x_q = x_p \), and it will be dealt with separately as a degenerate case in Section F. The intersections between \( L_q^0 \) and \( L_p^i \), \( \sigma_p^i = (a_q^i, b_q^i) \), for \( i = 0, 1 \), are calculated. Geometrically, the vertical line segment in the strip, one of whose endpoints is one of the intersections \( \sigma_p^i \) in the dual space, corresponds to a digital line with the two critical points \( p \) and \( q \) in the primal space. This shows that the digital lines corresponding to the vertical line segments between the two intersections \( \sigma_q^0 \) and \( \sigma_q^1 \) in the strip always contain \( q \) as an inlier.

D. Finding the Largest Consensus Set in a Strip. To know the number of inliers within the digital lines with a critical point \( p \), we check the intersections \( \sigma_q^0 \) and \( \sigma_q^1 \) of \( L_q^0 \) for all \( q \in S \setminus \{p\} \) with the strip boundaries, \( L_p^0 \) and \( L_p^1 \). We use two values \( f_q^i \) for \( i = 0, 1 \), as illustrated in Figure 8.

\[ L_p^0 = \{(a, b) : x_p a + b + y_p + w = 0\}, \]
\[ L_p^1 = \{(a, b) : x_p a + b + y_p - w = 0\}, \]

as illustrated in Figure 8.
which is set to be 1 if $L_{q}^{0}$ enters the strip from $L_{p}^{i}$ and $-1$ if $L_{q}^{0}$ leaves the strip from $L_{p}^{i}$.

Once the intersections $\sigma_{q}^{i} = (a_{q}, b_{q})$ and the associated value $f_{q}^{i}$ for $i = 0, 1$ are calculated for all $q \in S \setminus \{p\}$, we sort all the triples $(a_{q}^{i}, b_{q}^{i}, f_{q}^{i})$ in increasing order by using $a_{q}^{i}$ as keys. As for determining the location of the maximum number of inliers, a function $F(a)$ is used; after initially setting $F(a) = 1$ for every $a$, since we already know that $p$ is an inlier, then the value $f_{q}^{i}$ is added to $F(a)$ for $a \geq a_{q}^{i}$ in the above sorted order. By looking for the maximum value of $F(a)$, we obtain the parameter set $(a, b)$ corresponding to the maximum optimal consensus set for a critical point $p$. In this section, we consider that all $L_{q}^{0}$ enter or leave a strip at different $a$. The degenerate cases such that many lines $L_{q}^{0}$ enter or leave a strip at the same $a$ will be described in Section F.

**E. Algorithm.** We now present Algorithm 1 in Figure 10. Input is a set $S$ of discrete points and a distance value $w$ of our digital line model. Output is a set $V$ of parameter values $(a^{F}, b^{F})$ corresponding to the fitted digital lines of that give the optimal consensus sets. In the algorithm, we consider another strip bounded by $L_{p}^{0}$ and $L_{p}^{1}$ as well, as seen in Steps 4, 9, and 21. We remark that, because $b_{q}^{i}$ is not used for the sorting step and can be calculated from $a_{q}^{i}$, we do not have to store it for each intersection. Simply for a candidate of the optimal consensus set, we calculate it as shown in Steps 21 and 22. Note that, depending on the strip, we calculate different $b^{F}$ because of the translation difference $w$ between the two strips. We also remark that Algorithm 1 provides us with the set of parameter pair values $(a^{F}, b^{F})$ of all the fitted digital lines of (3) that give the optimal consensus sets.

The time complexity of the algorithm is $O(N^{2} \log N)$, because we have $N$ points in $S$ and each $p \in S$ needs the complexity $O(N \log N)$, for sorting at most $2N - 2$ different values $a_{q}^{i}$ for $q \in S$, $q \neq p$, and $i = 0, 1$. The space complexity is $O(N)$ because for each sorting we have at most $2N - 2$ different pairs $(a_{q}, f_{q})$.

Because all inputs can be given as integers or rational numbers, all computations in Algorithm 1 can be made by using only rational numbers. This guarantees that all results obtained by Algorithm 1 contain no numerical error. However, degenerate cases may occur, which are discussed in the followings.
F. Degenerate Cases. In this section, we deal with degenerate cases, which are not considered in Algorithm 1. They are summarized as follows:

- Suppose that $p$ and $q$ such that $x_q = x_p$, $L_q^0$ is parallel to $L_p^0$. If $L_q^0$ is between $L_p^0$ and $L_p^1$ (resp. $L_p^2$), then we set the initial value of the function $F(a)$ to 2 when $l = 1$ (resp. $l = 2$) because $q$ is an inlier for any $a$. Otherwise, we set it to 1, as described in Algorithm 1, because $q$ is an outlier for any $a$.

- When many lines $L_q$ enter or leave a strip at the same moment $a$, all the positive values $f_q^i$ of that moment must be added to the function $F(a)$ at once (Step 17 in Algorithm 1), and the value $F(a)$ is compared with the current maximum value $\text{Max}$ (Step 18 in Algorithm 1). Note that all the negative valued $f_q^i$ of the same moment $a$ must be added after the comparison to the function $F(a)$. Indeed such a point $q$ must be considered as an inlier until that moment.

Obviously, those modifications affect neither the time nor space complexity of the algorithm.

V. DIGITAL PLANE FITTING ALGORITHM

The algorithm is based on a similar idea to the one for 2D digital line fitting, presented in the previous section. The key idea for the extension to 3D digital plane fitting is treating the 3D problem as a 2D problem. In this section, we show how to reduce the dimension from three to two, and obtain an algorithm providing a $O(N^3 \log N)$ time and $O(N)$ space complexity.

A. Digital Plane Fitting in the Dual Space. A point $p = (x, y, z)$ in the primal space associates to a nonvertical plane

$$P_p = \{(a, b, c) : xa + yb + c + z = 0\}$$

in the dual space. Conversely, a nonvertical plane in the primal space associates to a point in the dual space. Similarly to a digital line, a digital plane defined by (4) is regarded as a set of nonvertical parallel planes whose normal vectors are $(a, b, 1)$ and whose $z$-intercepts are between $-c$ and $w - c$, and it forms a vertical line segment of length $w$ in the dual space as illustrated in Figure 11. The problem of finding the optimal consensus set for digital plane fitting in the primal space is then equivalent to searching the position of the vertical line segment of length $w$ such that it intersects with the maximum number of planes in the dual space.

We now need a search procedure for an optimal segment. Thanks to Proposition 2, we know that, for any consensus set, there

![Algorithm 2: Digital plane fitting](algorithm_2.png)

Vol. 21, 45–57 (2011) 51
exists a digital plane featuring at least three critical points, among which at least two are on one of the support planes. Thus, taking two different points \( p, q \) from \( S \) in the primal space, we first consider all the digital planes on which both \( p \) and \( q \) are critical points on the same support plane. In the dual space, digital planes having two critical points \( p, q \) forms two strips, which will be described in Section B. We then explain how digital planes with two critical points \( p, q \) appear in the strips when they have a third critical point \( r \) so that the sub-problem becomes the same as the 2D sub-problem.

**B. Strips Made from a Critical Point Pair.** Let \( p = (x_p, y_p, z_p) \) and \( q = (x_q, y_q, z_q) \). In the dual space, they represent two planes \( P_p \) and \( P_q \), defined by (7). They intersect in a line \( L_{pq}^0 \) if \( p \) and \( q \) are chosen such that \( (x_p - x_q)^2 + (y_p - y_q)^2 = 0 \); otherwise, \( P_p \) and \( P_q \) are parallel, and no intersection line can be found. The intersection line \( L_{pq}^0 \) is represented by the following equation:

\[
L_{pq}^0 = \{ v = (a, b, c) : v = u + td, t \in R \},
\]

where

\[
d = (x_p - x_q, y_p - y_q, 1)
\]

and \( u = (u_p, u_q, u) \); \( u \) is a chosen point on \( L_{pq}^0 \). For example, if \( x_p y_q \neq x_q y_p \), by fixing \( u = 0 \), \( u_q \) and \( u \) are automatically found since \( u \) is on both \( P_p \) and \( P_q \).

Once \( L_{pq}^0 \) is found, then, all the digital planes on which both \( p \) and \( q \) are critical points on the same support plane in the primal space correspond to the set of all the vertical line segments of length \( w \) having one of its endpoints on \( L_{pq}^0 \) in the dual space, as shown in Figure 12. We see in the figure that the set of such digital planes, therefore, forms two strips in the plane \( Q_{pq} \) that contains \( L_{pq}^0 \) and the direction parallel to the \( c \)-axis. Taking the \( d \)-axis in \( Q_{pq} \) as the orthogonal one to the \( c \)-axis, such \( Q_{pq} \) is illustrated in Figures 12 and 13. Each strip on \( Q_{pq} \) illustrated in Figure 13 is bounded by two parallel lines, \( L_{pq}^1 \) and \( L_{pq}^2 \) for \( i = 1, 2 \), which are represented by:

\[
L_{pq}^1 = \{ v = (a, b, c) : v = u + e + td, t \in R \},
\]

\[
L_{pq}^2 = \{ v = (a, b, c) : v = u - e + td, t \in R \},
\]

where \( e = (0, 0, w) \). Note that they correspond to \( L_{pq}^0 \) and \( L_{pq}^1 \) of (5) and (6) for the 2D case.

**C. Digital Planes with Critical Point Triplets.** Hereafter, we focus on one of the strips in \( Q_{pq} \) because the following discussion is valid for both strips. Let us consider the strip bounded by \( L_{pq}^0 \) and \( L_{pq}^1 \), as illustrated in Figure 13. According to Proposition 2, we choose a point \( r \in S \}\{p, q \} to be the third critical point of a fitted digital plane such that \( r \) is not collinear with \( p \) and \( q \); the collinear case will be handled separately as a degenerate case in Section F. Any point \( r \) in the primal space is represented by the line \( L_r \) in \( Q_{pq} \) in the dual space, which is the intersection between \( P_r \) and \( Q_{pq} \), as shown in Figure 13. We see in this figure that \( L_r \) intersects each of the strip boundaries, \( L_{pq}^0 \) and \( L_{pq}^1 \), if it is not parallel to \( L_{pq}^0 \); the parallel case will be dealt with separately as a degenerate case in Section F. The intersections between \( L_r \) and \( L_{pq}^i \), \( i = 0, 1 \), are calculated from \( L_{pq}^0 \) and \( P_r \). Geometrically, the vertical line segment in the strip, one of whose endpoints is one of the intersections \( r_i \) in the dual space corresponds to a digital plane with three critical points \( p, q \) and \( r \) in the primal space. This indicates that the digital planes corresponding to the vertical line segments between the two intersections \( r_0^p \) and \( r_1^p \) in the strip always contain \( r \) as an inlier. This structure is already seen in the 2D case.

**D. Finding the Largest Consensus Set in a Strip.** Similarly to digital line fitting, to know the number of inliers within the digital planes with two critical points \( p \) and \( q \), we check the intersections \( r_i^p \) and \( r_i^q \) of \( L_r \) for all \( r \in S \}\{p, q \} with the strip boundaries, \( L_{pq}^0 \) and \( L_{pq}^1 \). We use the similar function \( f_r \) for \( r \in S \}\{p, q \}, \( i = 0, 1 \), and sort the quadruples \( (a_i^p, b_i^p, d_i^p, e_i^p) \) corresponding to the maximum number of inliers, we also use the similar function \( F(a) \) (resp. \( F(b) \) depending on the key selection) after initially setting \( F(a) = 2 \) for every \( a \). We obtain the parameter set \( (a, b, c) \) corresponding to the maximum optimal consensus set for a pair of critical points \( p, q \) and \( r \). The degenerate cases such that many lines \( L_r \) enter or leave a strip at the same intersection will be treated in the same manner as the 2D case.

**E. Algorithm.** We now present Algorithm 2 in Figure 14, which is easily obtained by modifying Algorithm 1. Input is a set \( S \) of discrete points and a distance value \( w \) of our digital plane model. Output is a set \( V \) of parameter values \( (a^C, b^C, c^C) \) corresponding to the fitted digital planes that represent the optimal consensus sets. In the
algorithm, we consider another strip bounded by $L_{pq}^0$ and $L_{pq}^2$ in Steps 5, 10, and 22. We remark that, because $c_i$ is not used for the sorting step and can be calculated from $a_i$ and $b_i$, we do not have to store it for each intersection.

In Steps 11 and 15, we only show the case where $a_k$ is used as keys for sorting. However, if $Q_{pq}$ is perpendicular to the $a$-axis, all $a_k$ has the same value. In such a case, as mentioned above, we use $b_k$ as keys instead of $a_k$. The time complexity of the algorithm is $O(N^3 \log N)$, because we have $N$ points in $S$ and each pair of $p$ and $q$ in $S$ needs the complexity $O(N \log N)$ for sorting at most $2N - 4$ different values $a_r'$ for $r \in S \{p, q\}$ and $i = 0, 1$. The space complexity is $O(N)$ because for each sorting we have at most $2N - 4$ different triples $(a_k, b_k, f_k)$.

All computations in Algorithm 2 can be also performed using only rational numbers since all inputs can be given as integers or rational numbers. This causes the following degenerate cases.

![Figure 17](image1.png)

**Figure 17.** An original image (left), and its optimal consensus set, in red color, of digital line fitting (right). [Color figure can be viewed in the online issue, which is available at wileyonlinelibrary.com.]

![Figure 18](image2.png)

**Figure 18.** A polygonal contour image with noise (left), and its result after six iterations of applying our method: the optimal consensus set obtained after each iteration is in red, blue, yellow, pink, cyan, and green, respectively (right). [Color figure can be viewed in the online issue, which is available at wileyonlinelibrary.com.]
F. Degenerate Cases. We consider the following three degenerate cases, where the second and third ones were already discussed for the 2D case in the previous section.

- If three points \( p \), \( q \) and \( r \) are colinear in the primal space, their associated planes \( P_p \), \( P_q \) and \( P_r \) have a line intersection in the dual space. Therefore, for any digital plane having \( p \) and \( q \) as its critical points also has \( r \) as its another critical point. Thus, the function \( F(a) \) initially set to 2 for the inclusion of \( p \) and \( q \) will be automatically increased by 1 because of the inclusion of \( r \).

- Suppose that \( p \), \( q \) and \( r \) are not colinear, but there is no intersection between \( L_{pq}^0 \) and \( L_r \) in \( Q_{pq} \); \( L_r \) is parallel to \( L_{pq}^0 \). We treat it in the same manner as the first degenerate case of digital line fitting; if \( L_r \) is between \( L_{pq}^1 \) and \( L_{pq}^2 \) (resp. \( L_{pq}^2 \)), then we set the initial value of \( F(a) \) to 3 when \( l = 1 \) (resp. \( l = 2 \)); otherwise, we set it to 2.

- When many lines \( L_r \) enter or leave a strip at the same moment \( a \), we apply the same procedure as the second degenerate case of digital line fitting.

Those modifications affect neither the time nor space complexity of the algorithm.

VI. FEASIBLE DIGITAL LINE AND PLANE PARAMETERS

Once we obtained an optimal consensus set \( C \) for digital line or plane fitting to a given point set \( S \), we need the parameters of digital lines and planes fitted to \( C \) for many applications. In general, the continuous line and plane model such as (1) and (2) are used for estimating them, for example, by applying the least squared method (Hartley and Zisserman, 2003) to \( C \). However, we must be careful because this may change inliers. In such a case, a new \( C \) should be recalculated from a new estimated line or plane, so that the iterative procedure may be necessary for renewing \( C \) with consecutive re-estimated line or plane parameters.

In our case, however, since we use the digital model such as (3) and (4) instead of (1) and (2), we do not need such an estimation procedure, and we need not worry that parameter values obtained...
by $C$ may produce a different $C$. We can obtain all feasible solutions for the parameters of digital lines (resp. planes) fitted to an obtained optimal $C$ by simply looking for all feasible solutions $(a, b)$ (resp. $(a, b, c)$) that satisfy the inequalities of (3) (resp. (4)) for all $(x, y) \in C$ (resp. $(x, y, z) \in C$).

Such feasible solutions of digital lines and planes are called preimages. It is known that preimages of digital lines have interesting properties. For instance, a preimage of a digital line forms a convex polygon in the dual space that has at most four vertices (Dorst and Smeulders, 1984). However for digital planes, the structure of their preimages are more complex than that of digital lines (Gerard et al., 2008); we even do not know the maximum number of vertices or facets of a convex polyhedron that constitutes a preimage of a digital plane.

VII. EXPERIMENTS

This section presents the 2D and 3D experiments. We cannot avoid using colors in the figures shown in this section, which can be seen correctly at the on-line version of the article.

A. 2D Noisy Image of Digitized Lines. We first tested our method with an image of size $102 \times 102$ originally made from two digital lines defined by a set of points $(x, y) \in \mathbb{Z}^2$ satisfying either $0 \leq \frac{1}{2}x + y + 50 \leq w$ or $0 \leq -\frac{1}{2}x + y + 50 \leq w$, $w = 0.999$. We then randomly added and removed 2000 points as noise for the image, and finally obtained 1800 points. Our method is applied to fit a digital line to these points. The optimal consensus set is found using our method, as shown in Figure 15; it has 87 inliers. From those 87 inliers, we also calculated a set of feasible parameters of fitted digital lines; it is given as the convex polygon in the parameter space $(a, b)$ of (3) whose vertices are $(-1/99, -4751/99)$, $(0, -49)$, $(0, -48)$, $(1/99, -4852/99)$.

We compared our result with that of RANSAC. For comparison, the tolerance of RANSAC is set to 0.5; this value specifies the maximum distance of inliers from a fitted line. In this experiment, we use the continuous line model of $ax + by + c = 0$ as in conventional RANSAC methods, and the vertical or horizontal distance as well as our method. Figure 16 shows the RANSAC results after 37,587 iterations. The number of inliers is 34, and the parameters of the line are: $a = -0.131175$, $b = 0.149704$, $c = -0.989991$. It should be noted that with our method all the feasibility parameters can be exactly computed from the inliers, while RANSAC finds only one parameter set. Moreover, the 34 inliers obtained by RANSAC are far from the optimal result of our digital line. In fact, this is due to the fact that RANSAC is based on a random sampling, which provides no guarantee of optimality. However, the computation time is relatively rapid, thanks to its probabilistic strategy.
Thus, in cases where there is a lot of noise, RANSAC should be avoided, whereas the use of RANSAC may be justified when it is sufficient to obtain an approximate solution for practical reasons.

**B. 2D Real Image.** We then tested our method with respect to a real image, as shown in Figure 17 (left), whose size is 520 × 693. Before applying our method, edge detection and mathematical morphological filtering are done for this image; the number of points in the image after this preprocessing is 5572 points. Our method is then applied to fit a digital line to the set of points. Figure 17 (right) shows the optimal consensus set, which includes 602 inliers, for digital line fitting. The distance $w$ was set to 1.

**C. 2D Polygonal Contour Images.** We also tested polygonalization using our method. It is tested using an iterative procedure by applying our method: after each iteration, we take the inliers off and apply our method to the remaining points. Figure 18 (left) shows the original polygonal contour image containing some noise whose size is 497 × 456. Figure 18 (right) shows the result after six iterations of applying our method for the polygonalization. The consensus set obtained after each iteration is colored in red, blue, yellow, pink, cyan, and green, respectively. The number of all points is 1960, and the sizes of the consensus sets are 297, 264, 186, 180, 119, and 104, respectively. The distance $w$ is set to be 1.

**D. 3D Real Images.** For the 3D experiments, we applied our proposed method to two example data, such as a 3D discrete point cloud and a 3D binary digital image. The first example is a 3D discrete point cloud in Figure 19, which is obtained after a planar surface segmentation of a range image of blocks (Kenichi et al., 2008). The number of points in the cloud is 12,859, and they are segmented into 13 planar surfaces, which are illustrated in Figure 19 with points in different colors, except for those colored in light green that are detected as edge points. For each of these 13 sets, we fitted a digital plane. We see the corresponding planes in Figure 20, and the number of points for each segmented surface and the size of its optimal consensus set in Table I. In Figure 21, we also see that the fitted plane for the blue segmented surface points in Figure 19: inliers are colored blue while outliers are in pink.

We also applied our method to a 3D image extracted from a polymer foam observed in X-ray micro-tomography, on which homotopic thinning and surface decomposition were applied (Plougonven et al., 2006). Figure 22 shows a cross section of the original image and Figure 23 shows a 3D binary image obtained after homotopic thinning and surface decomposition; the image is cut into two parts for visualization. Among around 400 sets of points forming surfaces in the entire image, we choose a part, as illustrated in Figure 24, including 17 decomposed surfaces for digital plane fitting. We show the fitted planes in Figure 25, and the number of points and the optimal consensus set size for each segmented surface in Table II. For both the examples, we set $w = 1$.

VIII. CONCLUSIONS

In this article, we have exposed a new method for line and plane fitting on discrete data such as bitmap images using a DG approach. The DG approach allows practitioners to separate effects due to digitization on the one hand and noise on the other. Using our approach, we have proposed an optimal fitting method from the point of view of the maximal consensus set; we are guaranteed to fit a digital line or plane with the least amount of outliers. The 3D algorithm is based on the same idea as the 2D algorithm however some extensions are done to adapt the algorithm to a 2D dual problem and to cope with the different degenerate cases. The 2D and 3D algorithms have a complexity that are identical to parameter-less traditional plane-fitting algorithms such as LMS regression (Rousseeuw, 1984), but allows us to define a digital line or plane exactly, in the presence of outliers. Future work will include improving algorithmic complexities and more complete applications such as optimal polygonalization or polyhedrization by choosing a good value for $\omega$ automatically, and image registration considering all feasible digital line and plane parameters.

ACKNOWLEDGMENTS

This work was accomplished while the first author was a post-doc at Université Paris-Est, Laboratoire d’Informatique Gaspard-Monge, ESIEE-CNRS, Paris. A preliminary version of this article was presented at the 13th International Workshop on Combinatorial Image Analysis (Zrour et al., 2009a).

The authors thank Mr. John Chaussard, who supplied the 3D image of decomposed surfaces extracted from a polymer foam used in the experiments. A part of this work has been supported by the French National Research Agency projects, ANR-05-BLAN-0071(SURF), and BLAN07-2-184378 (MICROFISS). The authors would like also to thank MEXT Fund for Promoting Research on Symbiotic Information Technology.
